Abstract

Airborne observations over the Amazon Basin showed high aerosol particle concentrations in the upper troposphere (UT) between 8 and 15 km altitude, with number densities (normalized to standard temperature and pressure) often exceeding those in the planetary boundary layer (PBL) by one or two orders of magnitude. The measurements were made during the German-Brazilian cooperative aircraft campaign ACRIDICON-CHUVA on the German High Altitude and Long Range Research Aircraft (HALO). The campaign took place in September/October 2014, with the objective of studying tropical deep convective clouds over the Amazon rainforest and their interactions with atmospheric trace gases, aerosol particles, and atmospheric radiation.

Atmospheric Chemistry and Physics Discussions

Aerosol enhancements were observed consistently on all flights during which the UT was probed, using several aerosol metrics, including condensation nuclei (CN) and cloud condensation nuclei (CCN) number concentrations and chemical species mass concentrations. The UT particles differed in their chemical composition and size distribution from those in the PBL, ruling out convective transport of combustion-derived particles from the BL as a source. The air in the immediate outflow of deep convective clouds was depleted in aerosol particles, whereas strongly enhanced number concentrations of small particles (<90 nm diameter) were found in UT regions that had experienced outflow from deep convection in the preceding 5-72 hours. We also found elevated concentrations of larger (>90 nm) particles in the UT, which consisted mostly of organic matter and nitrate and were very effective CCN.

Our findings suggest a conceptual model, where production of new aerosol particles takes place in the UT from volatile material brought up by deep convection, which is converted to condensable species in the UT. Subsequently, downward mixing and transport of upper tropospheric aerosol can be a source of particles to the PBL, where they increase in size by the condensation of biogenic volatile organic carbon (BVOC) oxidation products. This may be an important source of aerosol particles in the Amazonian PBL, where aerosol nucleation and new particle formation has not been observed. We propose that this may have been the dominant process supplying secondary aerosol particles in the pristine atmosphere, making clouds the dominant control of both removal and production of atmospheric particles.

1. Introduction

Aircraft measurements in the upper troposphere (UT) have consistently shown large regions with very high aerosol particle number concentrations, typically in the tens of thousands of particles per cm^3, with the strongest enhancements reported in tropical and subtropical regions (Clarke et al., 1999; Andreae et al., 2001; de Reus et al., 2001; Twohy et al., 2002; Krejci et al., 2003; Lee et al., 2003; Young et al., 2007; Ekman et al., 2008; Yu et al., 2008; Froyd et al., 2009; Weigelt et al., 2009; Borrmann et al., 2010; Clarke and Kapustin, 2010; Mirme et al., 2010; Weigel et al., 2011; Waddicor et al., 2012; Reddington et al., 2016; Rose et al., 2017). In most cases, these elevated aerosol concentrations were in the nucleation and Aitken mode size ranges, i.e., at particle diameters smaller than about 90 nm, with maxima typically between 20 and 60 nm (e.g., de Reus et al., 2001; Lee et al., 2003; Weigel et al., 2011; Waddicor et al.,

2012). They generally occur as layers of a few hundred to thousand meters in thickness, often extending over large horizontal distances, and are found over continents as well as over the most remote oceanic regions. The high concentrations of these aerosols in the UT are of great significance for the climate system, because they make this region an important reservoir of particles for the transport either downward into the planetary boundary layer (PBL) (Clarke et al., 1999; Clarke et al., 2013; Wang et al., 2016a) or upward into the Tropical Transition Layer (TTL) and the lower stratosphere (Weigel et al., 2011; Randel and Jensen, 2013), where they can grow into the optically and cloud-microphysically active size range.

Where enhanced particle concentrations in the accumulation mode (larger than about 90 nm) have been observed, the enrichment was frequently attributed to sources of sulfur dioxide (SO_2) and other combustion emissions, especially biomass burning, based on correlations with combustion tracers, such as carbon monoxide (CO), and airmass trajectories (e.g., Andreae et al., 2001; Clarke and Kapustin, 2010; Weigel et al., 2011; Clarke et al., 2013). After having been lofted to the UT by deep convection, particles in this size range can be transported over hemispheric distances, because removal processes are very inefficient at these altitudes (Andreae et al., 2001; Clarke and Kapustin, 2010).

The enhanced particle concentrations in the ultrafine (UF) size range (here defined as particles smaller than 90 nm), on the other hand, cannot be explained by transport from the lower troposphere, since they far exceed typical concentrations in the PBL and generally are too short-lived to survive deep convection and long-range transport. Therefore, nucleation and new particle formation (NPF) from gas phase precursors brought into the UT by the outflow from deep convection have been proposed as the source of these enhanced particle concentrations (Clarke et al., 1999; Twohy et al., 2002; Krejci et al., 2003; Lee et al., 2003; Young et al., 2007; Froyd et al., 2009; Merikanto et al., 2009; Weigel et al., 2011; Waddicor et al., 2012; Carslaw et al., 2017). High actinic flux, low preexisting aerosol surface area, and low temperatures make the UT an environment that is highly conducive to nucleation and NPF.

The nature of the gaseous species involved in particle nucleation and growth has been the subject of some debate (Kulmala et al., 2006). Most of the earlier papers attributed the nucleation to H_2SO_4 in combination with H_2O and NH_3, especially in marine and anthropogenically influenced regions, where a sufficient supply of sulfur gases from either DMS oxidation or pollution

sources is available (e.g., Clarke et al., 1999; Twohy et al., 2002; Lee et al., 2003; Merikanto et al., 2009). However, there is growing evidence that, in most cases, there is not enough H_2SO_4 available to explain the observed rates of growth. Therefore, the condensation of organics has been proposed to dominate particle growth after nucleation, especially over unpolluted vegetated areas such as the Amazon Basin (Ekman et al., 2008; Weigel et al., 2011; Waddicor et al., 2012; Murphy et al., 2015).

In fact, H_2SO_4 may not always be required even to be the initially nucleating species. Recent studies conducted as part of the Cosmics Leaving OUtdoor Droplets (CLOUD) project have shown that organic vapors alone can produce particle nucleation (Kirkby et al., 2016) and that nearly all nucleation throughout the present-day atmosphere involves ammonia or biogenic organic compounds (Dunne et al., 2016). Highly oxygenated multifunctional organic compounds (HOMs) formed by ozonolysis of α-pinene were found to nucleate aerosol particles, especially when aided by ions. Extremely low volatility organic compounds (ELVOCs, which may be at least in part identical to HOMs) are also produced from the O_3- or OH-initiated oxidation of biogenic volatile organic compounds (BVOCs) (Jokinen et al., 2015). Following nucleation by the lowest-volatility species, with increasing particle size the condensation of progressively more volatile compounds is facilitated by the decrease in the Kelvin effect (Tröstl et al., 2016). These laboratory studies were confirmed by field observations at a mountain site in the free troposphere, where NPF was found to take place through condensation of HOMs, albeit from anthropogenic precursor VOCs, within 1-2 days after being lofted from the PBL (Bianchi et al., 2016).

The production of particles in the UT may be a key component of the atmospheric budget of optically and cloud-microphysically active aerosols, especially in pristine or relatively unpolluted regions, as was suggested in a modeling study by Merikanto et al. (2009). Studies in the Amazon have shown that NPF almost never takes place under clean conditions in the PBL over the Amazon Forest (Zhou et al., 2001; Martin et al., 2010; Andreae et al., 2015) and rarely occurs over the taiga forest in remote Siberia (Heintzenberg et al., 2011). Over the Amazon, downward transport of aerosols from the free troposphere (FT) has been identified as an important, if not dominant, source of particles to the lower troposphere (LT) (Zhou et al., 2001; Roberts and Andreae, 2003; Wang et al., 2016a). In turn, the concentrations of aerosols in the PBL have a pronounced influence on the characteristics of convection and thereby influence cloud radiative

forcing and atmospheric dynamics (Sherwood, 2002; Rosenfeld et al., 2008; Fan et al., 2012; Rosenfeld et al., 2014; Stolz et al., 2015; Cecchini et al., 2017).

Understanding the processes that control the aerosol burden in the pristine atmosphere is an essential prerequisite for assessing the magnitude of the climate forcing by anthropogenic aerosols, since it forms the baseline from which anthropogenic forcing is derived. Because of the strong non-linearity of the relationship between particle number concentration and cloud-mediated aerosol effects, the uncertainty regarding the aerosol burden of the pristine atmosphere is the largest contributor to the uncertainty in estimates of anthropogenic aerosol climate forcing (Carslaw et al., 2013; Carslaw et al., 2017). For example, model calculations suggest that the inclusion of ion-induced particle formation from biogenic HOMs in the natural atmosphere reduces the cloud-albedo radiative forcing by about one-third because of the higher albedo calculated for the clouds in the pre-industrial atmosphere (Gordon et al., 2016).

In this paper, we present the results of aerosol measurements made in the upper troposphere across the Amazon Basin during the ACRIDICON-CHUVA campaign on the German HALO aircraft during September and October 2014 (Wendisch et al., 2016). ACRIDICON stands for “Aerosol, Cloud, Precipitation, and Radiation Interactions and Dynamics of Convective Cloud Systems”; CHUVA is the acronym for “Cloud Processes of the Main Precipitation Systems in Brazil: A Contribution to Cloud Resolving Modeling and to the GPM (Global Precipitation Measurement)”. We characterize these UT aerosol particles in terms of their microphysical and chemical properties, and contrast them with the LT aerosols. From their spatial distribution and their relationship to deep convection and convective outflow, we derive hypotheses about their mode of formation. Finally, we discuss the role of upper tropospheric aerosol formation in the life cycle of the atmospheric aerosol.

2. Methods

The observations discussed in this paper were collected aboard the HALO aircraft (http://www.halo.dlr.de/), a modified Ultra Long Range Business Jet G 550 (manufactured by Gulfstream, Savannah, USA). Because of its high ceiling altitude (up to 15 km) and long endurance (up to eight hours with a scientific payload), HALO is capable of collecting airborne measurements of cloud microphysical and radiative properties, aerosol characteristics, and chemical

tracer compounds in the upper troposphere, in and around tropical deep convective clouds. The aircraft and its instrumentation are described in the ACRIDICON-CHUVA overview paper by Wendisch et al. (2016).

In-situ meteorological and avionics data were obtained at 1 Hz from the BAsic HALO Measurement And Sensor System (BAHAMAS). This data set includes pressure, temperature, wind direction and speed, humidity, water vapor mixing ratio, aircraft position, and altitude. All concentration data have been normalized to standard temperature and pressure (T = 273.15 K and p =1000 hPa).

2.1. The HALO aerosol submicrometer inlet (HASI)

All aerosol sampling was conducted using the HALO aerosol submicrometer inlet (HASI), designed for HALO by the German Aerospace Center (DLR) in collaboration with enviscope GmbH (Frankfurt, Germany) with the aim of providing up to 30 l min^{-1} sample air flow (divided over four sample lines) to aerosol instruments mounted inside the aircraft cabin. HASI samples the air on top of the fuselage outside of the aircraft boundary layer. The air stream is aligned in the inlet using a front shroud and decelerated by a factor of approximately 15. Four sample tubes with 6.2 mm outer diameter and frontal diffusors protrude into the decelerated air stream. The design goal is to allow regulating the sample airflow in each of the four sample lines to achieve isokinetic sampling conditions according to the actual speed of the aircraft. Since the automatic adjustment had not been implemented at the time of the field experiment, the flow was fixed to values providing near-isokinetic sampling for typical flight conditions based on geometric considerations and preliminary flow simulations for the initial design of the inlet. The geometric design should prevent large cloud droplets and ice crystals from entering the sample lines directly. The inlet position is located in the shadow zone for larger ice crystals, which precludes artifacts by shattering and break-up of larger ice particles at the inlet tip (Witte, 2008). Judging from the first measurements with HASI, it appears that measurements of interstitial aerosol in liquid clouds are affected by artifacts, while in ice clouds there is no indication for such artifacts. The data selection procedures to exclude artifacts are discussed in section 2.2.

2.2. Condensation nuclei

Condensation nuclei (CN) number concentrations (N_{CN}) were measured using the Aerosol Measurement System (AMETYST). This system was designed to provide an instrument package for HALO to measure basic microphysical properties of the ambient atmospheric aerosol (integral number concentration, sub-micrometer size distribution, fraction of non-volatile particles, and particle absorption coefficient). AMETYST includes four butanol-based condensation particle counters (CPCs, modified Grimm CPC 5.410 by Grimm Aerosol Technik, Ainring, Germany) with flow rates of 0.6 and 0.3 l min^{-1}, configured with different nominal lower cutoff diameters at 4 nm and 10 nm (set via the temperature difference between saturator and condenser). In addition, two differential mobility analyzers (Grimm M-DMA) with a nominal size range between 5.5 and 350 nm using ^{241}Am radioactive sources as aerosol neutralizers are part of the system.

Two of the four CPCs are generally set to measure the integral particle concentrations, while for the two other CPCs the configuration is selectable depending on measurement priorities. They can be used either as detectors for the DMAs or for additional integral concentration measurements. The DMAs can either be set to select specific diameters or operated as a DMPS (differential mobility particle sizer) system scanning the size distribution at predefined diameter steps. The integration times at each step have to be chosen such that meaningful statistics can be achieved depending on the measurement strategy. AMETYST also includes an optional thermodenuder, which heats a section of the sample line to 250°C for the measurement of the non-volatile particle fraction.

The raw CPC data are corrected using an empirical, pressure-dependent flow correction to account for changes in the volume flow at different flight altitudes (D. Fütterer, PhD thesis, in preparation). Particle losses in the sampling lines have been estimated with the particle loss calculator by von der Weiden et al. (2009). Accounting for these effects leads to an increase of the effective cutoff diameter for all CPCs. The effective cutoffs are calculated as a convolution of the pressure-dependent CPC counting efficiency and the size-dependent transmission efficiency of the sample lines. The data reported here were taken by the CPC operated at 0.6 l min^{-1}, with a nominal cutoff of 4 nm. Due to inlet losses, the effective cutoff diameter increases to 9.2 nm at 1000 hPa, 11.2 nm at 500 hPa, and 18.5 nm at 150 hPa. This implies that the present setup of

AMETYST essentially does not detect nucleation mode particles below 10 nm at low altitudes and below 20 nm in the UT. Typical uncertainties of CPC number concentration measurements are estimated to be of the order of 5 to 10% (Petzold et al., 2011).

To eliminate artifacts from cloud hydrometeors and bias from local pollution, we excluded measurements using the following criteria: (1) All cloud passages below 6 km were removed. During passages through water clouds, the CPCs showed erratic, unreasonably high number concentrations that are probably caused by droplet shattering at the probe tip. Cloud passages were identified from the observation of elevated concentrations of particles >3 μm using the hydrometeor probes (see below). (2) In the mixed phase and ice phase regimes, all cloud passages were inspected for possible shattering artifacts, and suspect data were rejected. Cloud passages through pure ice clouds did not show evidence of hydrometeor shattering. (3) The flight segments during departure and approach to Manaus airport were removed to avoid pollution from the airport and its surroundings. (4) Flights segments through the Manaus urban plume, which was sampled during joint flight experiments with the DOE G1 aircraft and in the course of tracer studies in the PBL, were excluded in order to provide a sampling representative of the dry season atmosphere over the Amazon Basin away from local pollution. (5) Fire plumes that were sampled deliberately to study fresh emissions were not analyzed for this paper. (6) Segments where the aircraft passed through its own exhaust were also excluded from the data analysis.

2.3. Aitken mode aerosol size spectra

To obtain aerosol size spectra for particle sizes up to 300 nm, the DMAs within AMETYST were connected to two of the CPCs and operated in scanning mode for selected flight sequences (especially during longer flight legs, where relatively homogeneous conditions can be assumed). The size range covered by the scans was typically between 20 and 300 nm diameter in nine steps. To improve the time resolution, the two DMPS were usually set to scan the same sequence in opposite direction. The DMPS data are then analyzed taking into account a correction for multiple charges following Wiedensohler (1988) after correcting the measured concentrations to standard atmospheric conditions. To derive modal parameters for the particle size distribution, a bi-modal log-normal fit to the data points was computed.

Atmospheric Chemistry and Physics Discussions

2.4. Accumulation mode aerosol particles

For the purposes of this paper, we define the accumulation mode as the particle size range from 90 nm to 600 nm and the total number concentration in this size class as the accumulation mode number concentration, N_{acc}. The particle concentrations in this range were measured with an optical particle counter (OPC), the Ultra High Sensitivity Aerosol Spectrometer (UHSAS; Droplet Measurement Technologies, Inc., Longmont, CO) (Cai et al., 2008; Brock et al., 2011). The UHSAS combines a high-power infrared laser (λ=1054 nm) and a large solid angle range in sideways direction for the detection of light scattered by individual particles. Due to the resulting almost monotonic increase of instrument response with particle size, the UHSAS enables high-resolution measurements (100 selectable channels). The high laser intensity enables the detection of particle diameters down to about 60 nm, with the upper limit being approximately 1 µm. Particle concentrations of up to 3000 cm^{-3} are recorded without significant counting coincidence losses (Cai et al., 2008). The airborne instrument version is mounted in an under-wing canister and equipped with a forward facing diffusor inlet. The slowed airflow is subsampled by a second inlet at approximately isokinetic conditions. The sample is not actively dried before the measurement, but due to combined heating effects the measured diameters can be assumed to be close to their dry diameters (Chubb et al., 2016). The UHSAS was calibrated with monodisperse polystyrene latex (PSL) spheres of known refractive index and size. The evaluation of the OPC calibration results and the derivation of realistic uncertainty estimates for the OPC size distributions is outlined in a recent study by Walser et al. (2017). Due to changes in the laser and instrument parameter settings during the campaign, only the size range from ~90 nm to ~600 nm is considered here.

2.5. Cloud condensation nuclei

The number concentration of CCN (N_{CCN}) was measured with a continuous-flow streamwise thermal gradient CCN counter (CCNC, model CCN-200, DMT, Longmont, CO, USA) (Roberts and Nenes, 2005; Rose et al., 2008). The CCN-200 consists of two columns, in which particles with critical supersaturations (S) above a preselected value are activated and form water droplets. Droplets with diameters ≥ 1 µm are detected by an optical particle counter (OPC) at the exit of the column. The inlet flow rate of the column used was 0.5 L min^{-1} with a sheath-to-aerosol flow ratio of 10. The water pump was operated at the CCNC setting of “high” liquid flow.

Atmos. Chem. Phys. Discuss., https://doi.org/10.5194/acp-2017-694
Manuscript under review for journal Atmos. Chem. Phys.
Discussion started: 1 August 2017

Variations in ambient pressure have a strong influence on the S inside the CCNC. For this purpose, a novel constant pressure inlet without significant particle losses was deployed on HALO. The instrument was calibrated before, during, and after the campaign at different pressures and flow rates according to Rose et al. (2008). For the data used in this study, we sampled from the HASI inlet and measured at S = 0.52±0.05% and a time resolution of 1 Hz.

Since the flow in the instrument was kept constant for the data used here, the error in S resulted from the calibration uncertainty, as described by M. Pöhlker et al. (2016); it is estimated to be in the range of 10%. According to Krüger et al. (2014), the error in N_{CCN} is based on the counting error of the measured particle number and is 10% of N_{CCN} for large concentrations; given that mostly low concentrations prevailed, the mean error was about 20% of N_{CCN}.

2.6. Cloud droplet and ice particle measurements

While measurements of liquid water and ice hydrometeor concentrations are not a subject of this paper, they were used to determine whether the aircraft was sampling inside clouds and if so, whether the cloud particles were liquid or frozen. For this purpose, we used data from the Cloud Droplet Probe (CDP) and the Cloud and Aerosol Spectrometer (CAS-DPOL), both of which are based on the principle of forward scattering detection. The CDP detects particles with sizes from 3 µm to 50 µm, and classifies them into size histograms of bin widths between 1 and 2 µm. The CAS-DPOL covers the size range of 0.6-50 µm in 17 bins of varying width. The probes are described in Voigt et al. (2017) and probes and data correction techniques in Weigel et al. (2016).

Information regarding the ice particle properties was obtained from the Particle Habit Imaging and Polar Scattering Probe (PHIPS-HALO), a single-particle cloud probe that measures microphysical and angular light scattering properties of individual particles (Abdelmonem et al., 2016). The instrument is composed of a stereoscopic imager that takes two brightfield images from the particles under a viewing angle difference of 120°. Simultaneously to collecting the images, the scattering part of the instrument measures the angular scattering function of the particles from 18° to 170° with an angular resolution of 8°. The optical resolution of the imager is about 2.5 µm.

2.7. Aerosol mass spectrometer

For in-situ chemical analysis of submicrometer aerosol particles a compact time-of-flight aerosol mass spectrometer (C-ToF-AMS) (Drewnick et al., 2005; Schmale et al., 2010) was operated onboard HALO. The C-ToF-AMS was sampling through the HASI inlet for ambient aerosol measurements. The aerosol particles enter the instrument via a pressure-controlled inlet and are focused into a narrow beam by an aerodynamic lens. In the vacuum chamber, the particles are flash-vaporized and the resulting gas-phase molecules are ionized by electron impact. The ions are guided into the Time-of-Flight mass spectrometer, separated by their mass-to-charge ratio, and detected by a microchannel plate detector. The C-ToF-AMS was operated with a time resolution of 30 seconds, providing mass concentrations of particulate organics, nitrate, sulfate, chloride, and ammonium.

2.8. Refractory black carbon

An eight-channel Single Particle Soot Photometer (SP2) was used to detect and quantify refractory black carbon (rBC) particles using laser-induced incandescence (Stephens et al., 2003; Schwarz et al., 2006). The instrument measures the time-dependent scattering and incandescence signals produced by individual aerosol particles when crossing a Gaussian-shaped laser beam (Nd:YAG; $\lambda = 1064$ nm). The particles containing rBC cores absorb the laser light and evaporate within the optical chamber emitting thermal radiation (incandescence). The peak intensity of the incandescence signal, recorded by two photomultiplier tubes over two different wavelength intervals, is linearly proportional to the mass of the rBC in the particle (Laborde et al., 2013). The instrument is sensitive to rBC cores in the nominal size range of 70 - 500 nm mass-equivalent diameter, assuming a density of 1.8 g cm^{-3}. The SP2 also detects the intensity of the light scattered by the particles using an avalanche photo-detector in order to determine the optical size of purely scattering particles in the diameter range of 200 - 400 nm.

The SP2 incandescence signal was calibrated several times (at the beginning, during, and at the end of the campaign) using size-selected fullerene soot particles. The scattering signal was calibrated using either spherical polystyrene latex size standards (208, 244, and 288 nm) or ammonium sulfate particles of different diameters selected by a differential mobility analyzer (DMA).

Manuscript under review for journal Atmos. Chem. Phys.
Discussion started: 1 August 2017

2.9. Trace gases

Ozone (O_3) was measured by a dual-cell ultraviolet (UV) absorption detector (TE49C, Thermo Scientific) operating at a wavelength of 254 nm. Signal differences from a cell with the sample air and a parallel cell with ozone-scrubbed air are used to infer the concentration of O_3. Sample air was drawn into the instruments through the standard HALO gas inlet via a Teflon PFA line using an external pump at a nominal flow rate of 1 l min^{-1}. The calibration of the instrument is traceable to the O_3 standard of the Global Atmosphere Watch station at Hohenpeißenberg, Germany. The data output of the instrument is corrected for the temperature and pressure in the absorption cells. The precision of the O_3 measurements is 2% or 1 ppb, whichever is larger, the accuracy is 5%. Details on the use of this instrument can be found in Huntrieser et al. (2016).

Carbon monoxide (CO) was detected with a fast-response fluorescence instrument (AL5002, Aerolaser, Garmisch, Germany) (Gerbig et al., 1999). The detection of CO is based on the excitation of CO at 150 nm using a CO_2 resonance UV lamp. The fluorescence light is detected by a UV-sensitive photomultiplier. The CO detector was calibrated in-flight using onboard calibration and zero gas sources. Data are recorded at 1 Hz. The precision and accuracy are 3 ppb and 5%, respectively.

Nitrogen monoxide (NO) and total reactive nitrogen (NO_y) were measured by a dual-channel chemiluminescence detector (CLD-SR, Eco Physics). For the NO_y channel, the chemiluminescence detector is combined with a custom-built Au converter which reduces all oxidized reactive nitrogen species to NO (Ziereis et al., 2000). Detection of ambient NO is performed via reaction with O_3 in a chamber and the luminescence signal of the excited NO_2 produced by this reaction. Both detector channels are equipped with a pre-reaction chamber for determination of cross-reactions of O_3 with interfering species. Sampling of ambient air is conducted via a standard HALO gas inlet using a Teflon line. The precision and accuracy of the measurements depend on the ambient concentrations, typical values are 5% and 7% (NO) and 10% and 15% (NO_y), respectively.

2.10. Trajectories and air mass history analysis

Backtrajectories were calculated for each minute, starting at the location of the HALO aircraft and using the FLEXPART (“FLEXible PARTicle”) Lagrangian Particle Dispersion

Model version 9.02 (Stohl et al., 1998; Stohl and Thomson, 1999; Seibert and Frank, 2004; Stohl et al., 2005). Trajectories were driven by six-hourly analyses, interlaced with the three-hour forecasts, from the Global Forecast System (GFS) of the National Centers for Environmental Prediction (NCEP), provided on a 0.5 x 0.5 degree horizontal grid (http://www.nco.ncep.noaa.gov/pmb/products/gfs/, last accessed 8 Sep 2016). For each trajectory, 10,000 'particles' (infinitesimally small air parcels) are released and followed back in time for 10 days. Sub-grid-scale processes like convection and turbulence act stochastically on each 'particle', resulting in a trajectory location probability distribution at each point in time. For convenience, the location probability distribution is simplified using a clustering algorithm, calculating five cluster centers of most probable trajectory locations (Stohl et al., 2002). Additional trajectory calculations were performed using the HYSPLIT model (Stein et al., 2015) with NCEP GDAS1 data and model vertical velocities.

We examined the history of the sampled airmasses for interactions with deep convection using the FLEXPART trajectories and GOES (Geostationary Operational Environmental Satellite) imagery. Every one-minute flight position was traced back in time in one-hour steps up to 120 hours. Each position was then matched in time to the closest GOES-13 (Geostationary Operational Environmental Satellite) infrared brightness temperature (T_b). As a proxy for deep convection, we searched for cloud top T_b below –30 °C and looked up the minimum T_b in a 1°x1° box around the center of the back-traced parcel. An example of this procedure is available in the Supplement (Figs. S1-S3). From these data, we recorded the time difference between the moment that HALO was sampling the airmass and its encounter with deep convection, possibly including multiple contacts with deep convection. We also noted the "deepest convection" (minimum T_b) encountered by the parcels and their height at the time of the encounter, as well as the number of hours that the parcel was within boxes with deep convection ($T_b < –30$ °C).

3. Results and Discussion

3.1. The ACRIDICON-CHUVA campaign

The ACRIDICON-CHUVA flights covered most of the Amazon Basin, reaching from the Atlantic coastal waters in the east to near the Colombian border in the west, and from the Guy-

anas border in the north to the arc of deforestation in the south. The flight tracks of the flights analyzed in this paper are shown in Fig. 1, where the flight segments at altitudes >8 km are shown as heavier lines.

3.2. Synoptic situation and chemical context

3.2.1. Meteorological overview

During boreal summer, the Intertropical Convergence Zone (ITCZ) undergoes a seasonal northward shift towards the northernmost part of South America, so that almost all of the Amazon Basin is in the meteorological Southern Hemisphere. Examination of cloud top height and precipitation images showed that the ITCZ was located between about 4 and 12 °N during the campaign (6 Sep to 1 Oct 2014), but was often not very well defined over South America (worldview.earthdata.nasa.gov, accessed 13 Jan 2017). This seasonal shift establishes the large-scale thermodynamic conditions that define the dry season over the Amazon Basin, characterized by synoptic-scale subsidence, a relatively dry planetary boundary layer (PBL) and mid-troposphere, and warm temperatures at the top of the PBL, resulting in elevated convective inhibition energy (CINE) (Fu et al., 1999; Wang and Fu, 2007; Collow et al., 2016). During the dry season, there is less shallow convection, cloud cover, and rainfall than in the wet season, but the convection that does occur is more organized with pronounced vertical development because of the simultaneous presence of high convective available potential energy (CAPE) and high CINE (Machado et al., 2004; Collow et al., 2016; Giangrande et al., 2017; Zhuang et al., 2017). The deep convective cloud fraction peaks in the late afternoon and evening (1600LT to 2400LT) with a cloud fraction maximum between 9 and 13 km altitude and a minimum near and above the freezing level between 4 and 7 km (Collow et al., 2016; Zhuang et al., 2017).

During the ACRIDICON-CHUVA campaign, the intense warm sea-surface temperature (SST) anomaly that had earlier prevailed in the southern South Atlantic and a less intense cold SST anomaly in the northern South Atlantic and near the Equator were strongly reduced, and a warm SST anomaly in the equatorial Pacific was building to form the 2015 El Nino (see also Martin et al., 2016). Consequently, the pattern of wind and omega (vertical motion) field anomalies decreased to nearly normal conditions. However, during the campaign there was a clear northeast-southwest contrast with drier conditions in the northeast and wetter ones in the southwest, as seen in the columnar precipitable water anomaly data from the NCEP Climate Forecast

System Version 2 Reanalysis (Fig. 2) (Saha et al., accessed 20 March 2017). The majority of HALO flights were over the drier anomaly or the neutral region. As a consequence of this drier anomaly, these regions presented warmer temperatures and lower relative humidity than the normal climatology. The synoptic pattern during the campaign resulted in a spatial rainfall distribution with a meridional pattern, with more intense rainfall in the west, around 300 mm in September, and less than 100 mm in the eastern Amazon (Fig. 3). Nine cold fronts penetrated into Brazil during September, however, only two moved northward and they had little interaction with Amazon convection. Only the cold front on 20 to 23 September was able to organize convection in the south of the Amazon Basin.

Figures 4a and 4b show the low (850 hPa) and high (200 hPa) level wind fields during September 2014. The mean low-level flow at 850 hPa shows the typical easterly winds throughout the Amazon Basin (Fig. 4a), decelerating near the Andes and curving to the subtropics. At high levels (Fig. 4b), there is a weak anticyclonic circulation over the southern basin, featuring the initial increased deep convection in the transition from the dry to the wet season (September) and the development of the Bolivian High during the onset of the wet season (December to March) (Virji, 1981; Zhou and Lau, 1998).

During the research flights, HALO reached maximum altitudes of 12.6 to 14.4 km a.s.l., corresponding to potential temperatures between 352 and 360 K (Fig. 5), i.e., the bottom of the tropical tropopause layer (TTL). The vertical profiles of temperature and potential temperature were remarkably consistent between the flights, showing a fairly stable stratification up to about 8 km and a slightly weaker gradient in potential temperature above this altitude. Relative humidity shows a broad minimum in the region between 6 and 10 km. For comparison, the data from radiosonde soundings at Manacapuru (a site southwest of Manaus) are provided in the supplement (Fig. S4).

Based on the soundings, the mean height of the thermal tropopause during the campaign was 16.9±0.6 km, corresponding to a potential temperature of about 380 K. During September 2014, the mean CAPE was 1536 J kg^{-1} and the mean CINE value was 37 J kg^{-1}, the precipitable water was 42 mm, the lifting condensation level 919 hPa, and the bulk shear 4.8 m s^{-1} (difference between the mean wind speed in the first 6 km and 500 meters). These values give a clear idea

about the typical cloud base expected, the high instability, the need of a forcing due to the CINE, the high shear, and the amount of integrated water vapor.

In this paper, we use the following terminology to describe the different layers of the tropical atmosphere: The region from the surface to the convective cloud base (typically about 1.2 to 1.7 km during mid-day) is the planetary boundary layer (PBL), above which is the convective cloud layer (CCL), which typically reached to altitudes of about 4-5 km during our campaign. The region between the CCL and the TTL is the free troposphere (FT), which we subdivide into the middle troposphere (MT) between about 5 km and 9 km and the and the upper troposphere (UT) above ca. 9 km.

3.2.2. Airmass origins and history

For an overview of airmass movement in the UT over the central Amazon during the campaign, we obtained trajectory frequency statistics for airmasses arriving at altitudes between 10 and 14 km over the central Amazon Basin. The frequency analysis indicated that airmass movement in the upper troposphere was generally relatively slow and tended to follow anticyclonic patterns (Fig. 6), consistent with the 200 hPa streamlines shown in Fig. 4b. The frequency diagram for the 72-h trajectories initialized at 12 km altitude (Fig. 6a) shows that most airmasses had remained over the basin for the preceding three days (only about 1% of the endpoints fall outside of the basin). The 10 and 14 km statistics show essentially the same patterns (Supplement Figs. S5-S6), as do the individual trajectories calculated from the aircraft positions along the flight tracks (not shown).

The 120-h trajectory statistics (Fig. 6b) and the examination of the individual trajectories along the flight tracks indicate that the air sampled in the UT had followed a number of different general flow patterns before being sampled by HALO: 1) flow from the Pacific with an anticyclonic loop of variable extent over the basin, ranging from almost zonal west-to-east flow to a huge loop going as far south as Argentina and as far east as the Atlantic, and then returning to the basin (types A and B in Table 1), 2) flow from the Atlantic, often almost zonal (type C), 3) internal circulation within the basin, usually along anticyclonic loops, but sometimes erratic (type D), and 4) flow from the Caribbean, often following an anticyclonic pattern (type E). The flow patterns of the UT airmasses that were enriched in aerosol particles are given in Table 1.

3.2.3. Atmospheric chemical environment

The atmospheric chemical environment over the Amazon Basin shows a pronounced seasonal variation (Talbot et al., 1988; Andreae et al., 1990b; Talbot et al., 1990; Andreae et al., 2002; Artaxo et al., 2002; Martin et al., 2010; Andreae et al., 2012; Artaxo et al., 2013; Andreae et al., 2015). During the rainy season, regional biomass burning is at a minimum and biological sources dominate trace gas and aerosol emissions in the basin, resulting in often near-pristine conditions. The most significant pollution input during this season is long-range transport from North and West Africa, which brings in a mixture of mineral dust and emissions from biomass and fossil fuel burning (Talbot et al., 1990; Wang et al., 2016b). In contrast, ACRIDICON-CHUVA took place during the dry season, when the Amazon Basin is impacted by a mixture of pollution from regional and remote sources (Andreae et al., 1988; Talbot et al., 1988; Artaxo et al., 2013). Deforestation and pasture-maintenance burning occurs throughout the basin, with the highest intensity along the southern periphery, the so called “arc of deforestation”. This creates a steep gradient of pollutant concentrations from the relatively moist and less densely developed northern and western basin to the drier and highly deforested and developed southern basin (Andreae et al., 2012).

Long-range transport from Africa affects pollution levels over the Amazon, in addition to regional sources. In the northern part of the basin, part of the 10-day backtrajectories arriving at the aircraft positions in the lower troposphere reach West Africa, where biomass burning and fossil-fuel emissions are prevalent, while other trajectories follow the northeastern coast of Brazil, which is densely populated. As one moves south, the influence of long-range transport from Southern Africa becomes more prevalent. This was clearly observed during flight AC19, which extended over the Atlantic east of the Brazilian coast. On this flight, an extended, 300-m thick layer of pollution at 4 km altitude was identified over the Atlantic with elevated rBC concentrations up to 2 μg m^{-3} (see section 3.4.4). The backtrajectories from the Amazon south of the Equator very frequently end in the central and eastern tropical Atlantic (see Fig. 3 in Andreae et al., 2015), where high levels of ozone, aerosols, and other pollutants from biomass burning have been documented by in-situ and satellite observations starting in the 1980s (Watson et al., 1990; Fishman et al., 1991; Andreae et al., 1994; Browell et al., 1996; Fishman et al., 1996).

Atmospheric Chemistry and Physics Discussions

509 **3.3. Vertical distribution of aerosol particle number concentrations over the Amazon Basin**

510 Figure 7a shows a statistical summary of all CN number concentrations (N_{CN}) observed
511 during the campaign. Data affected by local pollution and cloud artifacts have been removed as
512 discussed in section 2.2. (Additional information about the flight segments on which elevated
513 N_{CN} were encountered is provided in Table 1.) In the PBL, which typically reached heights of 1.4
514 to 1.8 km during the afternoon, mean N_{CN} ranged from ~750 cm^{-3} on the least polluted flights to
515 ~4500 cm^{-3} in the most polluted regions over the southern part of the basin. Above the PBL, CN
516 concentrations typically remained relatively high within the lower troposphere up to about 3-4
517 km, and then declined with altitude. N_{CN} reached a minimum of ~700 cm^{-3} at about 4-5 km alti-
518 tude everywhere over the basin. This aerosol minimum coincides with the minimum in cloud
519 cover that has been observed at and above the freezing level, which has been suggested to be as-
520 sociated with rain development by the Wegener-Findeisen-Bergeron process at this level
521 (Collow et al., 2016).

522 Above this level, we found a general increase in particle concentrations, such that above 8
523 km, N_{CN} were typically in the range of 2000 to 10,000 cm^{-3}. This altitude corresponds approxi-
524 mately to the 340 K potential temperature level, above which elevated CN concentrations had
525 also been found in previous studies (Borrmann et al., 2010; Weigel et al., 2011).

526 While the statistical plot in Fig. 7a shows a general particle enrichment in the UT, indi-
527 vidual vertical profiles show more complex structures (Fig. 7b). The highest N_{CN}, sometimes
528 reaching up to 65,000 cm^{-3}, were encountered in thin layers often only a few hundreds of meters
529 thick. A distinct example for such a layer is seen in the descent profile (segment A2) from flight
530 AC09 (Fig. 4b), with peak CN concentrations of ca. 35,000 cm^{-3}. Other profiles, e.g., the descent
531 profile from flight AC07 (segment G), show enhancements over a layer about 3 km thick, with
532 N_{CN} of 10,000 – 20,000 cm^{-3}.

533 The CN enrichments in the UT consist predominantly of ultrafine particles in the size
534 range below 90 nm. In contrast to N_{CN}, the enhancement of accumulation mode particles (N_{acc},
535 defined here as the particles in the size range 90 to 600 nm) in the UT is much less pronounced.
536 The concentration of accumulation mode particles in the LT typically ranged from ~500 to
537 ~3000 cm^{-3}, depending on the level of pollution (Fig. 8a). Like the vertical profile of N_{CN}, the
538 profile of N_{acc} also shows a decrease above the LT to a minimum around 4-5 km, followed by an

increase towards the upper troposphere. Over the more polluted regions in the southern basin, N_{acc} in the UT was often considerably lower than in the LT.

Figure 8b illustrates the different behavior of CN and accumulation mode particle number concentrations at the example of a sounding in the central Amazon Basin from flight AC19. In the LT, N_{CN} and N_{acc} have similar values and decline to a minimum at about 4.7 km. Above this altitude, N_{CN} shows several sharp concentration peaks, with one at about 7.4 km reaching concentrations around 65,000 cm^{-3}. These peaks are only weakly, if at all, reflected in N_{acc}, which shows a broad enhancement in the UT to values around 1000 cm^{-3}. Consequently, we find two types of aerosol enrichments in the UT: at one extreme, thin layers with extremely high N_{CN} values but no significant increase in particles larger than 90 nm, at the other, broad overall particle enrichments with modest values of both N_{CN} and N_{acc}.

3.4. Differences between UT and LT aerosols

The high concentrations of particles in the UT over the Amazon Basin beg the question of their origin. Three different mechanisms can be considered: vertical transport of particles from the PBL by deep convection, horizontal long-range transport from remote source regions, and in-situ new particle formation. To assess these possibilities, we discuss in the following sections the chemical and physical properties of the UT aerosols and contrast them with the LT aerosol.

A first argument against vertical transport as the dominant source mechanism for the large particle concentrations in the UT comes simply from the observed CN concentrations. Since we are using concentrations normalized to standard temperature and pressure, N_{CN} should not change with vertical transport alone, and the values measured in the UT should not exceed those measured in the PBL. The fact that CN concentrations in the UT across the entire Amazon Basin are higher than the PBL values we measured anywhere in the basin, often by very large factors, rules out vertical transport of particles from the Amazon PBL as the dominant source of UT particles.

3.4.1. Particle size

The particles in the UT have a very different size distribution from those in the LT, which also shows that they could not have originated from upward transport of PBL aerosols by deep convection. Unfortunately, a detailed analysis of the size distribution of the particles in the UT is

hampered by the significant losses of small particles in our inlet system. As discussed in section 2.2, the particle losses increase with altitude such that in the UT most of the particles below ca. 20 nm are lost in the inlet system before reaching the CPC. Because of a longer inlet tubing connection and lower sample flow, the losses were even more significant for the DMPS, and as a result of this and other operational limitations, valid particle size distributions are only available from the LT.

The DMPS measurements in the LT showed that the aerosol size distribution was dominated by an accumulation mode centered at about 190 nm, flanked by an Aitken mode with a maximum at about 80 nm (Fig. 9), in good agreement with the size distributions measured previously at ground level in the Amazon (Zhou et al., 2002; Rissler et al., 2006; Andreae et al., 2015; Pöhlker et al., 2016) and those obtained over the Amazon on the G1 aircraft during the GoAmazon 2014 campaign (Martin et al., 2016; Wang et al., 2016a). For comparison, we show size spectra from GoAmazon 2014 from Wang et al. (2016a), the only published size spectra from the FT over central Amazonia. Unfortunately, even these data reach only up to 5.8 km, the ceiling altitude of the G1 aircraft. In the PBL, these spectra were similar to our measurements from the LT. With increasing altitude, total particle concentrations increased and the size spectrum became dominated by an Aitken mode at ca. 50 nm (Wang et al., 2016a). A previous study over the northern Amazon in Suriname had also found a decrease in the modal diameter of the Aitken mode from ~70 nm in the LT to ~ 30 nm in the UT above 10 km (Krejci et al., 2003). Assuming that similar size distributions prevailed in the UT during ACRIDICON-CHUVA and given the fact that inlet losses limited our measurements to particle diameters >20-30 nm, it seems justified to conclude that our N_{CN} concentrations in the UT are actually lower limits and that the true concentrations might have been significantly higher.

In the absence of full size spectra, we use the ultrafine fraction [UFF, defined as the fraction of particles with diameters between 90 nm (the lower cutoff of the UHSAS) and ~20 nm (the lower cutoff of the CPC), i.e., UFF = $(N_{CN}-N_{acc})/N_{CN}$] as a metric for the contribution of the Aitken and nucleation modes to the total observed particle concentration. The summary profile plot (Fig. 10a) shows the dramatic difference between the UFF in the LT and UT: In the LT, the mean UFF is about 0.05 to 0.2, showing the dominance of the accumulation mode. The share of ultrafine particles increases throughout the middle troposphere, and in the UT they account for the vast majority of particles, with UFF values around 0.7 in regions where both N_{acc} and N_{CN} are

599 moderately enriched, and values approaching 1.0 in the layers with very high N_{CN}. This shows
600 up more clearly in individual profiles, e.g., the soundings in Fig 10b from flight AC18. The
601 highly enriched layers are represented by UFF peaks in the range of 0.7 to 1.0, whereas the back-
602 ground UT enrichment exhibits UFF values of 0.5 to 0.8. The highest UFF values were measured
603 in the very young aerosol layer in segment E2 at 13.5 km (Fig. 10b), with an estimated particle
604 age of about 1-5 hours (more on this layer in section 3.5.2).

605 3.4.2. Cloud nucleating properties

606 The cloud nucleating ability of aerosol particles depends both on their size and their
607 chemical composition. Here we focus on CCN concentrations at 0.52% supersaturation ($N_{CCN0.5}$),
608 which are dominated by the particles in the accumulation mode size range, but also include a
609 fraction of the Aitken mode. A full discussion of the CCN measurements during ACRIDICON-
610 CHUVA will be presented elsewhere (M. Pöhlker et al., 2017, in preparation).

611 Figure 11a shows the vertical distribution of CCN for the entire campaign, indicating
612 strong variability in the LT, a minimum at ca. 5 km, and elevated concentrations in the UT. The
613 $N_{CCN0.5}$ variability in the LT was related to the variable level of pollution, mostly from biomass
614 burning, which was much higher in the southern part of the basin than in the north. In contrast,
615 there was no systematic difference between the CCN concentrations in the UT above polluted
616 and relatively clean regions. Therefore, depending on the level of pollution in the lower tropo-
617 sphere, the $N_{CCN0.5}$ in the UT during our campaign were higher or lower than those in the LT.
618 This is illustrated at the example of $N_{CCN0.5}$ profiles from Flights AC09 and AC12+13, from a
619 clean region (AC09) and one polluted by biomass burning emissions (AC12+13), respectively
620 (Fig. 11b). While there was a large difference in the CCN concentrations in the LT, the values in
621 the UT were very similar between these flights, indicating that the CCN enrichments in the UT
622 are independent of the pollution levels in the LT.

623 The CCN concentrations at a supersaturation S=0.52% in the UT were consistently
624 greater than the corresponding values of accumulation particle number concentrations, N_{acc}, re-
625 sulting in a median $N_{CCN0.5}/N_{acc}$ ratio of 1.66 (quartile range 1.32 – 2.32, N=53,382) above 8 km.
626 This implies that some of the particles smaller than 90 nm are also able to nucleate cloud drops at
627 S=0.52%. Because size-selective CCN measurements were not performed during ACRIDICON-
628 CHUVA, it was not possible to derive the actual critical diameters and hygroscopicity factors (κ,

Petters and Kreidenweis, 2007) for the CCN on this campaign. However, a consistency check can be made using the measured chemical composition. As will be discussed in detail in section 3.4.4, the UT particles consist predominantly of organic material, with minor amounts of nitrate and very small fractions of sulfate. The hygroscopicity of particles consisting completely of organic matter can vary greatly, with κ between near 0 and about 0.3 (Jimenez et al., 2009). Our AMS measurements (see section 3.4.4) showed that the UT secondary organic aerosol (SOA) contains a substantial fraction of organics derived from the oxidation of isoprene (IEPOX-SOA) (Schulz et al., 2017), which has relatively high hygroscopicity ($\kappa \geq 0.1$) (Engelhart et al., 2011; Thalman et al., 2017). Assuming a conservative value of $\kappa_{org} \cong 0.1$, which had been found previously for the Amazon PBL (Gunthe et al., 2009; Pöhlker et al., 2016), pure SOA particles would have to have diameters of ≥80 nm to act as CCN at 0.52% supersaturation, whereas for pure ammonium sulfate particles ($\kappa \cong 0.6$), the critical diameter would be ca. 45 nm (Petters and Kreidenweis, 2007). At a typical organic mass fraction of 0.8 for the UT aerosol (see section 3.4.4), an effective κ of ca. 0.2, corresponding to a critical diameter of ~65 nm, is likely. Given the expected steep increase in particle concentration between the N_{acc} cutoff of 90 nm and the estimated critical diameter of 65 nm, a $N_{CCN0.5}/N_{acc}$ ratio of the observed magnitude appears thus quite reasonable.

The vertical distribution of the CCN fraction, i.e., the ratio $N_{CCN0.5}/N_{CN}$, shows a pronounced decrease with altitude (Fig. 12a), reflecting the smaller particle size in the UT. It also exhibits a strong inverse relation to the total particle concentration, N_{CN}. This is illustrated at the example of flight AC18 (Fig. 12b), where the data from different flight segments are plotted. Segments A and F (yellow and orange) are from soundings in the somewhat more polluted central part of the Amazon Basin, while B and C (green) are from the cleaner westernmost part and show the lowest CCN concentrations and the highest CCN fractions. Both soundings have high-CN layers at altitudes between 7 and 13 km, with N_{CN} up to almost 23,000 cm^{-3}, and correspondingly low $N_{CCN0.5}/N_{CN}$. Segment E2 (red) is from a layer that was intercepted downwind of a massive convective complex, with a transport time of 1-5 hours between the anvil and the aircraft (see section 3.5.2). This layer had N_{CN} values up to 45,000 cm^{-3}, CCN fractions down to 0.01, and UFF ≅ 0.98, suggesting that these recently formed particles were too small to act as CCN. This layer was embedded in a region of moderately elevated CN (segment E1 at 13-14 km; lilac), which had much higher $N_{CCN0.5}/N_{CN}$ (0.2-0.5) and lower UFF (0.6-0.8), indicating larger

particle sizes and likely a more aged aerosol. Segment D (blue), at 11-12 km altitude, had similar properties to E1. These observations point to the presence of two distinct aerosol populations in the UT. At one extreme are aerosols with very high N_{CN} and ultrafine fractions and low CCN fractions (e.g., E2), presumably representing newly formed particles with sizes too small to act as CCN. At the other extreme are populations with modest N_{CN}, but high UFF and CCN fractions, indicating a more aged aerosol with larger particles (e.g., E1 and D).

The existence of these two populations is confirmed in plots of $N_{CCN0.5}$ and $N_{CCN0.5}/N_{CN}$ against supersaturation. Examples are shown in Fig. 13a and 13b, with AC18-DD representing a segment dominated by larger and aged particles, AC07-F a region with high concentrations of small and younger particles, and AC09-AA a mixed case with short periods of very high N_{CN} over a background of moderately elevated particle concentrations. Even though the mean CN concentration exceeds 8900 cm^{-3} in AC07-F, the mean $N_{CCN0.5}$ in the same region is only 13 cm^{-3} and therefore the $N_{CCN0.5}/N_{CN}$ vs. S plot falls essentially on the baseline. In contrast, AC18-DD presents a fairly "classical" supersaturation spectrum, and AC09-AA is a mixed case with the measurements made during the N_{CN} peaks showing very low $N_{CCN0.5}/N_{CN}$.

In Fig. 13c and 13d, we compare the mean supersaturation spectra from the lower, middle and upper troposphere obtained on flights AC12 and AC13, which were taken on successive days over the same region and where the LT was influenced by biomass burning pollution. In the LT, the CCN fraction is in the range observed at ground level at the Amazon Tall Tower Observatory (ATTO) site (Pöhlker et al., 2016) and in close agreement with measurements in the southern Amazon during the biomass burning season (Vestin et al., 2007). In the UT, we observed low CCN fractions representing the regions with high N_{CN} and UFF, mostly at altitudes of 10-11 km, and higher CCN fractions at 12 km and above corresponding to a region with elevated CCN (cf. Fig. 11b, which shows the CCN concentrations from these flights). In the middle troposphere (5-8 km) we found intermediate CCN fractions, consistent with a mixture of LT and UT aerosols.

3.4.3. Volatility

On several flights (AC16, 18, 19, and 20), a second CPC was operated behind a thermodenuder at a temperature of 250 °C, in parallel to the regular CPC. The results of these measurements are shown in Fig. 14a in the form of the volatile fraction (VF), i.e., $(N_{CN} - N_{nonvol})/N_{CN}$,

690 plotted against altitude. In the LT, most particles are nonvolatile and the VF is typically between
691 10 and 20%. This is consistent with the behavior described by Clarke and Kapustin (2010) and
692 Thornberry et al. (2010), who found that aged combustion aerosols (from biomass of fossil-fuel
693 burning) are non-volatile and mostly in the accumulation mode size fraction. With increasing al-
694 titude, the VF increases, closely resembling the profile of the UFF. In the UT, the mean VF
695 reaches about 80%, and approaches 100% in the most highly enriched layers (e.g., segment E2).
696 In previous campaigns, high volatile fractions had also been observed in the tropical UT and
697 TTL, with the highest VF in the region between 340 and 360 K potential temperature, corre-
698 sponding to about 9-15 km (Borrmann et al., 2010; Weigel et al., 2011).

699 More detail can be seen when looking at data from an individual flight. In Fig. 14b we
700 show the profiles from AC18, which we had already discussed in the context of CCN concentra-
701 tions in the previous section. The profiles (segments A, B, C, and F) show the overall increase in
702 VF with height, with peak values at embedded high-CN layers. The freshest layer (E2), which
703 had the highest UFF, also has the highest VF. In contrast, segments D and E1, representing larger
704 UT regions with moderate CN enrichments, larger particles, and higher CCN fraction also have
705 lower VFs, between 0.4 and 0.7. A contribution from aged combustion aerosols can be ruled out
706 as source for the non-volatile particles in these layers, because the rBC concentrations are close
707 to zero (see below). As we will show in the next section, it appears that these low-volatility parti-
708 cles represent a more aged organic aerosol.

709 3.4.4. Chemical composition

710 As discussed above, the LT aerosol over the Amazon during the dry season is dominated
711 by the products of biomass burning, with increasing concentrations from north to south. This is
712 clearly reflected in its chemical composition, which is dominated by carbonaceous matter (or-
713 ganic and elemental carbon) and only contains minor fractions of inorganic species, such as po-
714 tassium, sulfate, and nitrate. Elemental or black carbon is a unique tracer of combustion emis-
715 sions and was measured on HALO in the form of refractory black carbon (rBC).

716 The vertical profile of rBC shows a sharp separation between LT and FT (Fig. 15). The
717 average rBC concentration in the region below 5 km was 0.31±0.29 μg m^{-3}, whereas in the FT
718 above 6 km it was 0.0026±0.0069 μg m^{-3} in terms of mass concentrations, and 99±92 cm^{-3} vs.
719 1.5±2.5 cm^{-3} in number concentrations of rBC particles. Interestingly, these concentrations over

the Amazon Basin are only slightly higher than the values measured over the tropical Western Atlantic during the Saharan Aerosol Long-range Transport and Aerosol-Cloud-Interaction Experiment (SALTRACE), June/July 2013: ca. 0.2 μg m^{-3} in the LT and ca. 0.001 μg m^{-3} in the FT (Schwarz et al., 2017), which suggests that a significant fraction of the rBC is entering the basin by long-range transport from Africa.

In 14 instances, elevated rBC concentrations were seen for short durations (usually less than 30 sec) in the UT. Most of the time, they occurred during cloud penetrations in the course of vertical cloud microphysics profiling. In the case of the flights over the northern half of the Amazon Basin, they could likely be attributed to sampling of HALO's own exhaust, based on the flight track and the presence of associated NO enhancements in the absence of strong enhancements of CO and other aerosol species (CCN, N_{acc}, N_{CN}). On flights over the southern Amazon (AC07, AC12, AC13, and AC20), where the PBL was more polluted and active fires were present, there were a few instances when elevated rBC coincided with peaks in CO and accumulation mode particles, which suggests upward transport of biomass smoke aerosols. In view of the scarcity of such events during our campaign and their modest rBC concentrations, it is clear that they do not represent a major source of combustion aerosol for the UT during our campaign. No elevated rBC concentrations were observed during the extensive outflow sampling legs on any of the flights. A detailed discussion of the rBC measurements during the campaign will be presented in a companion paper (Holanda et al., 2017).

The drop in rBC concentration by two orders of magnitude between LT and FT implies that rBC, and by extension other aerosols (which are likely even more prone to being removed by nucleation scavenging), are efficiently removed during deep convection and consequently that there is little transport of LT aerosols into the FT. Consequently, enrichments in N_{CN} and N_{acc} in the FT cannot be explained by vertical transport of particles from the FT.

The AMS measurements also show pronounced differences in the composition of the LT and UT aerosols (Fig. 16). In Table 2 we present a detailed analysis of the results from three flights, AC07 from a polluted region in the southern Amazon, and AC09 and AC18 from relatively clean regions in the northern and northwestern parts of the Basin, respectively. Organic aerosol (OA) is the dominant aerosol species in all three regions at all altitudes, as expected in an

area where biomass burning and secondary organic aerosol (SOA) production are the dominant sources.

In the LT, (ammonium) sulfates (SO4) are together with rBC the next most important species. Here, we see a clear difference between the BB-dominated region in the south (with high OA, ammonium [NH4], and rBC, and relatively low SO4) versus the northern basin, where SO4, likely from long-range transport, plays a more important role. The ratio OA/rBC in the LT is in the range 3-11, consistent with values from BB aerosols. The biomass burning marker, f_{60} (Schneider et al., 2006; Alfarra et al., 2007), is present in all the measurements from the LT, but always mixed with oxidized secondary organics. It should also be noted that the f_{60} marker is not an inert tracer but decays with time, and an observed background level of the f_{60} tracer is 0.3% of OA (Cubison et al., 2011).

In the UT, SO4 shows lower concentrations than in the LT, with the most pronounced difference on flights AC07 and AC18. The latter flights also show a large difference in the OA/SO4 ratio, which is around 10 in the UT and around 2 in the LT. Because of the high BB component in flight AC07, this ratio is also high in the LT on this flight. The most pronounced differences between UT and LT are seen in the nitrogen species. Ammonium is usually present in the BL, sometimes at considerable levels (e.g., on AC07), but always below the detection limit in the UT. In contrast, nitrate (NO3) is a minor species in the LT, whereas in the UT it is comparable or greater than SO4, so that the ratio NO3/SO4 is about an order of magnitude higher in the UT than in the LT. High concentrations of organics, especially oxidized organics, and nitrate had been seen previously in the UT by Froyd et al. (2009).

The nature of the nitrate signal in the UT cannot be definitely identified from our data. The absence of NH4 and the ratio of the peaks associated with ammonium nitrate make it unlikely that the NO3 signal represents ammonium nitrate (Fry et al., 2009; Bruns et al., 2010). It may be, at least to a large part, indicative of organonitrates, which have been shown to account for 15-40% of SOA mass in laboratory experiments (Berkemeier et al., 2016) and whose formation is enhanced at low temperatures (Lee et al., 2014).

A closer look at the aerosol-enriched layers in the UT from these flights reinforces these conclusions (Table 2). In these layers, the ratios OA/SO4 and NO3/SO4 can reach very high values, especially in the SO4-poor UT of flight AC07. On flights AC09 and AC18, we encountered

779 extended periods when N_{acc} and $N_{CCN0.5}$ were elevated, while N_{CN} did not show extremely high
780 values (AC09-AA, AC18-AA, and AC18-DD). The AMS data from these segments were gener-
781 ally similar to the UT averages, suggesting that they are representative of the ambient UT aero-
782 sols. The layers with very high N_{CN} on these flights (AC09-BB, AC09-EE, AC09-A1+A2, and
783 AC18-A1, AC18-A2, AC18-E2, AC18-F) also did not show significant differences from the UT
784 means on these flights, likely because the numerous, but very small CN in these layers did not
785 contain enough mass to influence the measurements in a detectable way.

786 We attempted to examine this hypothesis further by investigating the size dependence of
787 the AMS signals, but because of the small aerosol mass concentrations in the UT, size infor-
788 mation from the AMS data required extended integration periods, which precluded obtaining size
789 data from the relatively short segments with very high N_{CN}. The most robust size data were from
790 the segments where relative high N_{acc} concentrations prevailed over extended periods of time,
791 e.g., segment DD (Table 2) on flight AC18. Here, the organic aerosol (OA) showed a broad
792 mode between 80 and 250 nm, with a modal diameter at 150 nm. This confirms that the AMS
793 compositional data are dominated by the accumulation mode, while the particles that make up
794 most of the UF fraction in the UT do not have enough mass to provide a clear AMS signal. An
795 exception may be some segments on AC09 (BB and EE), where OA and NO3 data suggest a
796 mass mode between 60 and 120 nm. Here, the UFF is quite high (0.85 and 0.92, compared to
797 segment DD on flight AC18, where it was 0.61) suggesting a smaller and therefore younger aer-
798 osol population.

799 More detailed information on the origin of the organics in the UT aerosol can be obtained
800 from specific markers. In the UT, the BB marker f_{60} is typically not detectable, which in combi-
801 nation with the fact that the ratio OA/rBC is of the order of 1000, precludes a significant contri-
802 bution of aerosols from biomass burning or other primary combustion aerosols to the OA in the
803 UT. In contrast, the marker f_{82}, which is indicative of IEPOX-SOA formed by the photooxidation
804 of isoprene (Robinson et al., 2011; Hu et al., 2015), is found in the aerosol-enriched layers in the
805 UT, suggesting oxidation of isoprene and other biogenic volatile organic compounds (BVOC) as
806 source of the OA (Schulz et al., 2017). The plot f_{43} vs. f_{44} is frequently used to represent the ag-
807 ing of organic aerosols (Ng et al., 2011). In Fig. 17, we show the median locations of the LT and
808 UT aerosol in this plot, which indicates that both are fairly well aged and oxidized, with the UT
809 data plotting slightly towards less oxidized and younger values. This may reflect an overall

younger aerosol, or the admixture of recent material either by condensation on the accumulation mode particles or in the form of an external mixture of larger aged particles with small younger ones. The individual segments from flight AC18, which had the lowest OA/SO4 and NO3/SO4 ratios, also plot in this region, showing that they are dominated by a relatively well-aged aerosol. In contrast, segments AC09-AA, and AC07-AA1, AC07-AA2, and AC07–GG, which have the highest OA/SO4 and NO3/SO4 ratios and much higher N_{CN}, plot much further to the lower right indicating a less oxidized, fresher aerosol. On this flight, the concentrations of accumulation mode aerosols in the UT were relatively low, so that freshly formed aerosol could be more evident because of a lower background of aged aerosol.

In summary, the chemical composition data show that, while both LT and UT aerosols are dominated by aged organics, their sources must be different because the UT aerosol is essentially devoid of the combustion tracers, rBC and f_{60}, whereas the OA/rBC ratios in the LT are consistent with combustion aerosols. Nitrate is strongly elevated in the UT, and may consist to a large extent of organonitrates. NH4 is a significant component in the LT, whereas it is below the detection limit in the UT. Size-selective chemical analysis is difficult because of the low aerosol mass concentrations, but the available data suggest that the AMS measurements are dominated by the accumulation mode, and the strong N_{CN} enhancements are not distinctly seen in the AMS data. Chemical marker analysis shows the general absence of BB tracers in the UT, while the marker f_{82} indicates production of IEPOX-SOA from isoprene. Most of the UT organics are aged and oxidized, but in some of the CN-enriched layers, younger and less oxidized OA was evidenced by much lower f_{44}/f_{43} ratios. A detailed discussion of the AMS measurements during ACRIDICON-CHUVA will be presented in Schulz et al. (2017).

3.5. Relationship to Deep Convection

In the preceding section, we have documented the differences between the aerosols in the LT and the UT, which rule out the possibility that convective transport of PBL aerosols can be an important source for the UT aerosols. This opens the question about the source of these particles: are they the result of long-range transport from remote sources or do they originate over the Amazon Basin? In the latter case, are they directly released in the outflow from the convective clouds or are they produced by subsequent nucleation and growth in the UT?

For the larger particles in the accumulation mode, represented by elevated N_{acc} and $N_{CCN0.5}$ in the UT, long-range transport cannot be excluded, because such particles can have long lifetimes in the upper troposphere (Williams et al., 2002). While the absence of detectable rBC still rules out an origin from pollution aerosols lofted from the LT, they may have formed days or weeks ago by gas-to-particle formation mechanisms anywhere in the free troposphere. In contrast, the high concentrations of small UF particles that we observed with high frequency in the UT cannot come from distant sources, as they persist only for hours to a few days before growing to larger sizes and decreasing in concentration due to coagulation and dilution processes (Williams et al., 2002; Krejci et al., 2003; Ekman et al., 2006).

3.5.1. Aerosols in cloud tops, anvils and outflows

First, we consider the possibility of these particles having been produced already inside the clouds and released by outflow into the UT. In earlier studies, NPF had been shown to occur in ice clouds in the tropical/subtropical UT, especially in conditions where the available surface area of ice particles was relatively low (e.g., Lee et al., 2004; Frey et al., 2011). To look for this phenomenon, we examined the particle concentrations during passages through the upper levels of deep convective clouds and in the anvils directly attached to active cumulonimbus clouds (Cb). Our measurements during these passages consistently show lower CN and CCN concentrations than in the surrounding UT air, as exemplified in Fig. 18a by data from flight AC18. During this flight segment we performed multiple penetrations of the tops of growing Cb at altitudes between 10.7 and 12.0 km and temperatures in the range of 225 to 236 K. During each cloud passage (indicated in Fig. 18a by the ice particle concentrations) the aerosol concentrations decreased sharply, to values of N_{CN} around 800 cm^{-3} and $N_{CCN0.5}$ around 250 cm^{-3} during the longer cloud passages. (Here, we use $N_{CCN0.5}$ as proxy for the accumulation mode particles, since the N_{acc} measurements in clouds were perturbed by shattering at the probe tip, whereas the N_{CN} and $N_{CCN0.5}$ measurements showed no artifacts in ice clouds.) In the case of N_{CN}, the values in the cloud tops are about the same as the PBL concentrations measured in the same region, while for $N_{CCN0.5}$ they are significantly lower than the PBL values of around 400 cm^{-3}.

The same behavior was found for all cloud penetrations in the UT during the campaign. In particular, extensive cloud top and outflow sampling on AC09, AC15, and AC16 also showed

868 $N_{CCN0.5}$ values down to 160-250 cm^{-3} and N_{CN} values down to 600-1000 cm^{-3}. The lowest parti-
869 cle concentrations were seen in a large outflow sampled on AC13 (20:08-20:30 UTC), when
870 both N_{CN} and $N_{CCN0.5}$ reached values below 50 cm^{-3} (Fig. 18b). In this airmass, NO and NO_y
871 were strongly elevated indicating recent NO production by lightning in the large Cb from which
872 this outflow originated.

873 Given that the air sampled during the cloud passages had already mixed in by lateral en-
874 trainment some of the surrounding air with much higher particle concentrations (Bertram et al.,
875 2007; Yang et al., 2015), these low particle concentrations in the cloud tops and outflows are
876 clear evidence that in-cloud processes were a sink and not a source of particles in the size class
877 measureable with our instrumentation. A rough estimate of the scavenging efficiency of the con-
878 vective process can be gained by using CO as a conservative tracer. For example, on flight AC18
879 the PBL concentrations of CO and N_{CN} averaged ~120 ppb and 780 cm^{-3}, and the UT during the
880 cloud penetrations around 1900 UTC had CO ~95 ppb and N_{CN} ~1500 cm^{-3}. In the cloud, CO
881 rose to 108 ppb and N_{CN} dropped to 750 cm^{-3}. Following the approach of Bertram et al. (2007),
882 we can estimate that the fraction of PBL air in the center of the cloud was ca. 0.52, and that with-
883 out scavenging, $N_{CCN0.5}$ would be ca. 1130 cm^{-3}. From these values, a scavenging loss of 90% or
884 more of CCN can be estimated, in good agreement with previous studies (e.g., Andreae et al.,
885 2001; Yang et al., 2015), and with the absence of detectable rBC.

886 Flight AC20 was the only exception to this behavior. Here, CN were strongly enhanced
887 during cloud passages and even CCN were slightly elevated in some passages. The cloud that
888 was sampled on this flight appears to have been a pyrocumulus that had been ingesting fresh bio-
889 mass smoke, as suggested by the strongly elevated CO during the cloud passages. This flight will
890 be discussed as a separate case study below (section 3.6.).

891 While these results show that the high particle concentrations we observed in the UT
892 were not directly released from the cloud tops, they do not rule out the possibility that new parti-
893 cle formation had already started in the clouds or anvils. This is because the newly formed parti-
894 cles observed in the earlier studies were almost exclusively in the size range below 20 nm (Lee et
895 al., 2004; Frey et al., 2011). Since our measurements are limited to particle sizes >20 nm, we
896 would not have been able to detect such freshly nucleated particles, and therefore the earliest
897 phases of particle nucleation and NPF over Amazonia will have to be addressed in future studies.

Our data do show, however, that release of particles by hydrometeor evaporation following deep convection is not a net source of particles to the UT over Amazonia, in contrast to what was observed over the Indian Ocean region by Engström et al. (2008). Because the N_{CN} and $N_{CCN0.5}$ concentrations in the ambient air in the UT are actually higher than in the air detrained by the Cb clouds, the detrainment leads at least initially to a reduction in UT particle concentrations in the size class >20 nm. Only through subsequent NPF can this be reversed and deep convection then become a net source of UT aerosols.

3.5.2. Relationship between aerosol enhancements and airmass history

Connections between the presence of aerosol enhancements and the outflow from convective systems had been observed in some previous studies (de Reus et al., 2001; Twohy et al., 2002; Benson et al., 2008; Weigelt et al., 2009). We examined the connection between deep convection (DC) and the presence of high CN concentrations by a combination of backtrajectory calculations and the analysis of cloud-top temperatures from GOES-13 weather satellite images, similar to the approach used in some previous studies (de Reus et al., 2001; Froyd et al., 2009; Weigelt et al., 2009). We analyzed backtrajectories initialized at the aircraft locations where we had observed elevated aerosol concentrations, as listed in Table 1. Then we checked for each hour along the backtrajectories whether the airmass had crossed a region with DC (cloud top temperatures below -30 ºC). The results show that in almost all cases, the aerosol enriched airmasses had encountered deep convection within the last 120 hours.

In Fig. 19 we present the results from two flights (AC09 and AC18) as examples. We find that for all flight segments that showed high aerosol concentrations in the UT (dark shading), the airmasses had made contact with DC with cloud tops typically reaching about -80 ºC. Of course, given the abundance of convection over Amazonia, it is to be expected that most airmasses would have interacted with convection within 120 hours (such as the example shown in the Supplement Fig. S2). For comparison, over the northeastern United States during summertime, Bertram et al. (2007) had found that more than 50% of UT air had encountered DC within the previous 2 days.

The cumulative plot of the time since the most recent DC contact (Fig. 20a) shows that on all flights (except AC19, the flight over the Atlantic) almost all aerosol-enhanced air masses had seen DC within the last 30-40 hours. The cloud tops during these encounters typically reached -

928 70 to -80 ºC (Fig. 20b). In many cases, the airmass history analysis shows multiple contacts with
929 deep convection within the preceding 72 hours. It must be noted, however, that the physical in-
930 teraction between an UT airmass and a specific deep convective event is not represented in the
931 trajectory model and that the trajectory history preceding the most recent such encounter be-
932 comes much more uncertain.

933 In some cases, the airmasses could be tracked back to regions where the cold cloud en-
934 countered by the tracked airmass looked more like cirrus than identifiable deep convective out-
935 flow. The same favorable conditions for nucleation (low temperature, low pre-existing aerosol
936 surface) as in the outflow regions prevail also in native cirrus, and Lee et al. (2004) had reported
937 NPF in cirrus without immediate connection to DC. This might also have occurred in our cam-
938 paign, but it is usually difficult to distinguish cirrus and very aged outflow.

939 More specific information about the time required for particle production and the evolu-
940 tion of the aerosol populations in the UT can be derived from a close examination of the trajecto-
941 ries for individual flight segments. Flight AC18 provides some illustrative examples. The trajec-
942 tories of the first particle plumes encountered (A1 and A2, Table 1) had passed close to areas of
943 intense deep convection (-30 to -60 ºC) about 17-21 hours before sampling. Because it is likely
944 that the aerosol precursor substances are formed by photochemical reactions, we also looked at
945 the amount of time that the airmass was exposed to sunlight (Lee et al., 2003). Since the convec-
946 tive encounters occurred between 16LT and 00LT and the measurements were taken at about
947 11LT, the airmass had only about 5-7 h of sun exposure. Assuming that the formation of the par-
948 ticles required photochemical processes, this implies that about 5-7 h were sufficient to produce
949 particle concentrations above 20,000 cm^{-3} with sizes >20 nm. The enrichment in this case oc-
950 cured only in the particles sizes <90 nm, with a UFF of about 0.98, while N_{acc} remained at the
951 same levels as in the surrounding background FT. Segment F, near the end of the flight, was
952 sampling a similar region as A1, with a similar airmass trajectory. Since this segment was taken
953 near the end of the day, the airmass had experienced about 11 hours of sunlight. There is some-
954 what of a shift towards larger particles, but this might also be coincidental.

955 The air in segments B and C had traveled along similar trajectories as A1 and A2, but un-
956 fortunately there are no GOES images available for the time when they crossed the convective

region encountered by A1 and A2, and so no conclusions can be drawn for these segments. Segments D and E1 represent airmasses that had made multiple and extended convection encounters over the central and western Amazon during the past 3 days. Here, we find only weak enhancements in N_{CN}, but significantly elevated $N_{CCN0.5}$ and N_{acc}, with a UFF of 0.73 and 0.82, respectively, suggesting that coagulation and growth had taken place over this time period.

Some of the highest N_{CN} (up to ca. 45,000 cm^{-3}) and UFF (0.98) were found in Segment AC18-E2, which was sampling the air just a few hours downwind of a massive convective system that reached well above our flight altitude of almost 14 km. The air sampled here had traveled for about one hour after leaving the convective complex before being encountered by HALO and had been interacting with this complex for up to 5 h, all of them in daylight. As in A1, A2, and F, there was no detectable enhancement in aerosol mass, as represented by N_{acc} and $N_{CCN0.5}$. The strongest enhancement in aerosol mass, on the other hand, was seen in the early part of segment E1, which didn't show a strong increase in number concentration. The air during this segment had made its last contact with a convective system about 65-72 hours before sampling.

Another illustrative case is flight AC09 over a clean region in the northern Amazon. Segments A1-A3 sampled clear air that had DC contact about 16 and 60 hours ago and the UFF around 0.94 indicated a moderately aged aerosol. Segments B1 and B2 were taken in air immediately surrounding a Cb anvil, with previous DC contacts at about 14, 80, and 120 hours before. Here, the relatively low UFF of ~0.92 signaled no influence from the freshly outflowing air. Segments C, D, and E were in air close to a Cb, within its anvil, and in a large anvil/outflow, respectively. Otherwise, they had a DC contact history similar to B. Here also, the UFF remains fairly low, and there is no evidence of particle production directly in the anvil/outflow.

To summarize, our observations indicate that, while there is no evidence of immediate production of detectable particles (i.e., >20 nm) in the actual anvil or outflow, a small number of daylight hours are sufficient to produce very large concentrations of particles with sizes larger than about 20 nm in the FT. This is consistent with the observations made in the outflow of a convective complex off Darwin, Australia, where maximum Aitken concentrations were reported after ca. 3 hours since the outflow (Waddicor et al., 2012). During NPF events in the FT on the Jungfraujoch, high concentrations of particles >20 nm were observed about 4-6 hours after sunrise (Bianchi et al., 2016). In the FT over other regions, growth may be considerably slower; for

example the measurements over oceanic regions by Weigelt et al. (2009) showed that it took about 12 hours for particles >12 nm to reach their maximum concentrations.

Considerably longer times (a few days) are required, however, before increases are detectable in the size class >90 nm. The development of significant amounts of particles in the accumulation mode appears to take two days or more, in agreement with the observations of Froyd et al. (2009), who had found enhanced aerosol organic mass concentrations over the Caribbean in UT air originating from Amazonia after 2-4 days in the atmosphere. Since many, if not most of our trajectories remain over Amazonia for this amount of time, there is enough time available in the UT over the Amazon Basin to produce CCN-sized aerosols within the region, which can subsequently be transported downward or be exported to other regions.

3.5.3. Aerosol enhancements and chemical tracers

The relationship between new particle production and the input of boundary layer air is also reflected in a correlation between N_{CN} and CO. When taking all data above 8 km, this correlation is highly significant given the large number of data points (N=68,360) but not very close (r^2=0.52) because of the large variability of CO concentrations in the PBL and UT background between flights (Fig. 21). Closer relationships are obtained when looking at individual flights and especially at individual profiles within flights.

Weigel et al. (2011) had seen a strong correlation between CO and nucleation mode particles over West Africa and interpreted it as indication of anthropogenic inputs. In contrast, over Amazonia we have not seen any evidence that UT aerosol production shows any relationship to boundary layer pollution, and we interpret the correlation between N_{CN} and CO simply as reflecting the input of air from the PBL, which generally has higher CO concentrations that the UT, by the cloud outflow. An opposite relationship is generally seen between N_{CN} and O_3, which tends to be lower in the particle-enriched layer. We also see this as an indication of injection of air from the PBL, which generally has lower O_3 concentrations than the UT.

The nitrogen oxides show a complex relationship with the particle enhancements in the UT, as illustrated at the example of a flight segment from AC07 (Fig. 22). The highest NO concentrations are found in the Cb anvils or freshest outflows, as identified by significant concentrations of ice particles (e.g., at 2056, 2119, and 2154 UTC). In these regions, we typically observed particle minima, as discussed above. In these airmasses, NO has been formed very recently by

lightning, and the NO to NO_y ratios are usually still very high. Here, the particles are still depleted by convection scavenging and there has not been enough time for new particles to form, at least not in the size range detectable by our instrumentation. On the other hand, there is a strong positive relationship between NO_y and N_{CN}, as seen in Fig. 22 during the entire period from 2051 to 2210 UTC. Regions with high concentrations of new particles generally show elevated NO_y, typically in the range of 1 to 3 ppb, indicating that photochemical reactions have taken place that both produced new particles and converted NO to NO_y.

3.6. Flight AC20: A special case with NPF from biomass smoke

On flight AC20, HALO performed detailed sampling of the anvil and outflow of a large Cb over northern Rondonia, a state with a high incidence of deforestation burning. Numerous outflow penetrations around this Cb were made, and the ice particles sampled here could be clearly identified as freshly produced in the Cb top. The CN concentrations in the UT away from the outflow were unimpressive, typically in the range 2000 to 10,000 cm^{-3}. However, in sharp contrast to the other flights, where the air in the outflow always had been depleted in aerosol particles, on this flight the outflow often showed much higher CN concentrations, between 10,000 and 20,000 cm^{-3} (Fig. 23a). The concentrations of CCN and nonvolatile CN in the outflow were either the same as in the surrounding air or slightly higher, also contrasting with the observations on the other flights, where they had been depleted. Since the N_{CN} in the outflow were also much higher than in the PBL (~2000 cm^{-3}), entrainment of PBL air cannot explain the CN enrichment.

The mixing ratios of CO, NO, and NO_y were also elevated in the outflow (Fig. 23b), which in the case of CO and NO_y might be explained by inputs from the PBL, where CO and NO_y levels were around 120-200 ppb and 2-3 ppb, respectively. The NO values in the PBL, on the other hand, were only about 0.13 ppb, similar to the UT values, requiring an additional NO source for the outflow.

The explanation for this unusual behavior may be found in the layer between 11.5 and 12.5 km that was penetrated during both ascent and descent (Fig. 23c). In this layer, N_{CN} reached 30,000 cm^{-3}, CO was elevated to ~140 ppb, N_{acc} to 850 cm^{-3}, and NO_y to ~1.6 ppb. The data also suggest a slight enrichment in rBC, but this is close to the limit of detection. These values suggest that this is a detrainment layer polluted with biomass smoke, as we have often seen on previous campaigns over the burning regions in southern Amazonia (Andreae et al., 2004). An urban

origin of this pollution is unlikely, since the only town in the region, Porto Velho, lies about 50-100 km downwind of the sampling area. The enhancement ratios in this layer, however, differ from fresh biomass smoke. The ratio $\Delta N_{acc}/\Delta CO$ is ~6-12 cm^{-3} ppb^{-1} and the ratio $\Delta CCN/\Delta CO$ about 2.5 cm^{-3} ppb^{-1}, much lower than the typical ratios in fresh smoke, which are about 20-40 cm^{-3} ppb^{-1} (Janhäll et al., 2010), indicating removal of CCN-sized particles during the upward transport. In contrast, the ratio $\Delta CN/\Delta CO$ was about 350 cm^{-3} ppb^{-1}, almost an order of magnitude above the values typical of fresh smoke. These results suggest that biomass smoke was brought to the UT either from the strongly smoke-polluted PBL in this region or actually by a pyro-Cb over an active fire, and that the concentration of the larger particles was strongly reduced by scavenging, which allowed new particle formation in this smoke layer. The enrichments seen in the outflow penetrations at altitudes above the 12-km layer may be the result of entrainment of air from this layer or of rapid particle formation in situ. While we have this kind of observations from only one flight, which took place over the most polluted region sampled during this campaign, they are suggestive of the potential of rapid particle formation and growth in smoke detrainment layers, an issue that merits further study in future campaigns.

3.7. Conceptual model and role in aerosol life cycle

The discussion in the preceding sections can be summarized in a conceptual model of the aerosol life cycle over the Amazon Basin (Fig. 20). In the Amazon PBL, the classical nucleation events characterized by the rapid appearance of large numbers of particles <10 nm and subsequent growth into an Aitken mode (e.g., Kulmala and Kerminen, 2008) has never been reported, in spite of several years of observations by several teams (Martin et al., 2010; Rizzo et al., 2013; Andreae et al., 2015). This has been attributed to the low emissions of gaseous sulfur species in the basin (Andreae and Andreae, 1988; Andreae et al., 1990a), which result in H_2SO_4 vapor concentrations that are too low to induce nucleation (Martin et al., 2010). Nucleation of particles from organic vapors alone is not favored in the Amazonian PBL because of high temperatures and humidity as well as the competition by the condensation sink on pre-existing particles, which results in organic coatings on almost all primary and secondary particles in the Amazonian PBL (Pöschl et al., 2010; Pöhlker et al., 2012).

Cloud updrafts in deep convection bring air from the PBL into the middle and upper troposphere, where it is released in the convective outflow (Krejci et al., 2003). During this process,

most pre-existing aerosols are removed by precipitation scavenging, especially the larger particles that account for most of the condensation sink (Ekman et al., 2006). Most likely, VOCs with low and very low volatilities are also removed by deposition on hydrometeors, which provide a considerable amount of surface area inside the clouds (Murphy et al., 2015).

The outflow regions in the UT present an ideal environment for particle nucleation, as had already been suggested in some earlier studies (Twohy et al., 2002; Lee et al., 2004; Kulmala et al., 2006; Weigelt et al., 2009). The temperatures are some 60-80 K lower than in the PBL, which decreases the equilibrium vapor pressure of gaseous species (Murphy et al., 2015) and increases the nucleation rate. Based on classical nucleation theory and molecular dynamics calculations, Yu et al. (2017) have estimated an increase in nucleation rate by one order of magnitude per 10 K. Nucleation rate measurements in the CERN CLOUD chamber indicate a similar temperature dependence (Dunne et al., 2016). Because the preexisting aerosol has been depleted during the passage through convective clouds before being released into the UT from the cloud outflow, the low particle surface area in the UT presents very little competition to nucleation from a condensation sink (Twohy et al., 2002; Lee et al., 2003; Lee et al., 2004; Young et al., 2007; Benson et al., 2008).

The rapid transport of PBL air to the UT inside deep convective clouds facilitates lofting of reactive BVOCs from the Amazon boundary layer (Colomb et al., 2006; Apel et al., 2012). Here, the initially O_3- and NO_x-poor boundary layer air is supplied with O_3 by mixing with UT air and addition of NO from lightning, creating a highly reactive chemical environment. This mixture is exposed to an extremely high actinic flux due to the high altitude and multiple scattering by ice particles. Because of the low airmass at UT altitudes, the actinic flux is already very high shortly after sunrise. In this environment, rapid photooxidation of BVOCs and formation of ELVOCs/HOMs is to be expected. In laboratory studies, HOMs have been shown to be rapidly produced at fairly high yields both by ozonolysis of terpenes and by reactions with OH radicals (Ehn et al., 2014; Jokinen et al., 2015; Berndt et al., 2016; Dunne et al., 2016).

In the absence of measurements of the relevant gaseous sulfur species and the composition of the nucleating clusters, we cannot make firm conclusions about the actual nucleation mechanism. Over marine regions and polluted continental regions, the particles observed in outflows and in the UT were mostly identified as sulfates (Clarke et al., 1999; Twohy et al., 2002;

Kojima et al., 2004; Waddicor et al., 2012), and consequently H_2SO_4 has been proposed as the nucleating species. However, since in some cases this identification was based only on the volatility of the particles, they could have also consisted of organics or mixtures of organics and H_2SO_4. Over the Amazon, nucleation by H_2SO_4 cannot be excluded based on our observations, especially if there was already some SO_2 or H_2SO_4 present in the UT before the injection of the organic-rich PBL air. However, since the Amazonian BL contains very little SO_2, the sulfur species would have had to come from outside the region and thus they would have had the opportunity to be oxidized to H_2SO_4 and nucleate into particles during its travel in the UT well before entering Amazonia. It is therefore much more likely that the particles in the Amazon UT formed by homogeneous nucleation of organics, as has been suggested by several authors (Kulmala et al., 2006; Ekman et al., 2008; Murphy et al., 2015). Nucleation by formation of clusters containing both H_2SO_4 and oxidized organic molecules is of course also a possibility that we cannot exclude (Metzger et al., 2010; Riccobono et al., 2014). However, recent studies have shown that HOM compounds can nucleate to form particles even in the absence of H_2SO_4, especially in the UT (Bianchi et al., 2016; Kirkby et al., 2016), and nucleation of HOMs without involvement of H_2SO_4 has been suggested to be the dominant mode of new particle formation in the pre-industrial atmosphere by the modeling study of Gordon et al. (2016). The importance of ions produced from cosmic radiation in this nucleation process is still controversial (Lee et al., 2003; Yu et al., 2008; Bianchi et al., 2016; Kirkby et al., 2016).

Regardless of the actual nucleating species, H_2SO_4 or HOMs/ELVOCs, the growth of the particles observed in our campaign must have been dominated by organics, as shown by the composition of the aerosol measured by the AMS. The dominance of organics in the growth of aerosols in pristine environments has also been suggested on the basis of modeling studies, both for the lower troposphere (Laaksonen et al., 2008; Riipinen et al., 2012; Öström et al., 2017) and the UT (Ekman et al., 2008; Murphy et al., 2015). In particular, isoprene-derived SOA has been suggested to be important in the growth of sub-CCN-size particles to CCN (Ekman et al., 2008; Jokinen et al., 2015), which would be consistent with the prevalence of isoprene in the Amazonian PBL and our observations of IEPOX-SOA in the UT aerosol. As the particles grow, the decrease of the Kelvin (curvature) effect with increasing size of the growing particles implies that subsequently relatively more volatile organics can condense (Tröstl et al., 2016), in agreement with the observed high volatile fraction we observed in the upper tropospheric CN.

While in general the volatile fraction of the particles in the UT was very high, there were also regions with a significant fraction of particles that did not evaporate at 250 ºC (see section 3.4.3). These were dominated by relatively aged organics, which, based on the absence on detectable rBC, must also be of secondary origin. Such thermally refractory organics may explain the presence of non-volatile particles in the tropical UTLS, which had been observed in previous campaigns especially in the region above 360 K (Borrmann et al., 2010).

Once particles have nucleated in the UT and grown into the Aitken mode and in some cases even into the accumulation mode size ranges, they can be transported downward towards the lower troposphere both by general subsidence under the prevailing high pressure system over Amazonia and by downdrafts associated with deep convective activity. Large-scale entrainment of UT and MT air into the boundary layer has been suggested as the major source of new particles in marine regions (Raes, 1995; Katoshevski et al., 1999; Clarke et al., 2013). Over Amazonia with its high degree of convective activity, downdrafts are likely to play a more important role. Downward transport of UT air by downdrafts associated with deep convective activity has been shown to inject air with lower moisture content, lower equivalent potential temperature, and elevated O_3 into the PBL (Zipser, 1977; Betts et al., 2002; Sahu and Lal, 2006; Grant et al., 2008; Hu et al., 2010; Gerken et al., 2016). It would follow that the same mechanism also brings down aerosol-rich air from the UT into the PBL. Indeed, in a recent aircraft study over the central Amazon, this mechanism was shown to be an important source of atmospheric aerosols, predominantly in the Aitken mode, to the Amazonian PBL (Wang et al., 2016a). Here, they can continue to grow by condensation of BVOC-derived organics into the accumulation mode and become available as CCN, closing the aerosol cycle over Amazonia.

4. Summary and Conclusions

As part of the ACRIDICON-CHUVA 2014 aircraft campaign, we investigated the characteristics and sources of aerosols in the upper troposphere over the Amazon Basin. We observed regions with high number concentrations of aerosol particles (tens of thousands per cm^3 STP) in the UT on all flights that reached above 8 km. The aerosol enhancements were commonly in the form of distinct layers with thicknesses of a few hundreds to a few thousands of meters. Such layer structures are a common feature of the free troposphere and have been related to detrainment from deep convection and large-scale subsidence (Newell et al., 1999).

In other regions, upward transport of aerosols from the PBL had been suggested to be an important source of UT aerosols, based on the abundance of low-volatility particles (Clarke and Kapustin, 2010), TEM analysis of individual particles (Kojima et al., 2004), or modeling of cloud processes (Yin et al., 2005). Over Amazonia, however, the UT aerosol was fundamentally different from the aerosol in the LT, indicating that upward transport of PBL aerosols, especially combustion aerosols from BB, is not an important source of aerosols to the Amazonian UT.

The number concentrations of particles in the UT were often by several orders of magnitude higher than in the LT, and their size distribution was dominated by the Aitken rather than the accumulation mode. In contrast to the LT, the particles in the UT were predominantly volatile at 250 ºC and had much higher organics and nitrate contents. The extremely low concentrations of rBC in the MT and UT show that the aerosols above the LT are not combustion-derived and indicate that the low-volatility fraction must be representing secondary organics of extremely low volatility (ELVOCs/HOMs). Regarding the size class large enough to act as CCN (larger than 60-80 nm), we can conclude based on the absence of rBC and the lack of BB indicators in the AMS measurements that the enhanced CCN in the UT are not related to upward transport of combustion products, in contrast to most previous studies (e.g., Krejci et al., 2003; Engström et al., 2008; Clarke et al., 2013).

By analyzing the history of the particle-enriched airmasses and comparing the transport paths to GOES infrared imagery, we could show in almost all cases that these airmasses had been in contact with deep convective outflow. Measurements inside the cloud tops and the outflow anvils close to the clouds showed that the pre-existing aerosols in the ascending air had been almost completely scavenged by in-cloud processes, making the clouds initially a net aerosol sink. The near-complete scavenging is consistent with the hypothesized large water vapor supersaturation in pristine tropical deep convective clouds, which can nucleate particles that are much smaller than the commonly defined CCN (Khain et al., 2012).

Based on our measurements, we propose that BVOCs in the cloud outflow are rapidly oxidized to HOMs/ELVOCs, which because of the low temperatures and low condensation sink can readily nucleate new particles and grow to sizes ≥20 nm within a few hours, making deep convective clouds an indirect aerosol source. This had also been concluded based on a large statistical sampling of UT air in the Northern Hemisphere by the CARIBIC aircraft measurement

program (Weigelt et al., 2009). The importance of NPF in the UT for the budget of CN and CCN had been proposed previously on the basis of modeling studies (Yu et al., 2008; Merikanto et al., 2009; Carslaw et al., 2017), and is evident in the global enhancement of CN in the UT, especially in tropical regions, seen in compilations of data from numerous aircraft campaigns (Yu et al., 2008; Reddington et al., 2016). In this way, aerosol production by BVOC oxidation in the UT can provide the "missing source" of FT organic aerosol, which had been deduced from a mismatch between models and observations (Heald et al., 2005).

The high aerosol concentrations in the UT provide a reservoir of particles that are available for downward transport into the PBL both by large-scale downward motion and by convective downdrafts. In a recent study, we have shown that transport of aerosols by downdrafts from the free troposphere is an important, if not the dominant, source of particles to the lower troposphere (LT) over the Amazon (Wang et al., 2016a). The particles that are produced by this mechanism in the UT over the Amazon (and probably other tropical continents as well) can be transported globally due to their long lifetime in the UT (Williams et al., 2002; Clarke et al., 2013) and affect the microstructure of low-level clouds after they eventually descend into the PBL, possibly at very large distances from the source areas of their precursors.

Our study and the results of some previous studies (Lee et al., 2003; Froyd et al., 2009) suggest that UT aerosol production is especially important in the tropics because of the high rate of BVOC production and the abundance of deep convection, but its relevance may also extend to temperate and boreal regions. Our measurements both in the Amazon and at a remote site in central Siberia, distant from SO_2 emission sources and thus experiencing very low H_2SO_4 concentrations, show that classical nucleation events are very rare to absent at such sites and may not provide a strong source of new particles (Heintzenberg et al., 2011; Andreae et al., 2015; Wiedensohler et al., 2017). Consequently, the UT may be an important, possibly even the dominant source of tropospheric aerosol particles in regions that are not strongly affected by anthropogenic aerosols. This would assign clouds a central role in the aerosol life cycle, controlling both source and sink of aerosol particles, at least in regions of low anthropogenic pollution. Furthermore, the relevance of UT aerosol production may not be limited to the troposphere, because the UT and the TTL are also important reservoirs for the transport of particles into the lower stratosphere (Fueglistaler et al., 2009; Borrmann et al., 2010; Randel and Jensen, 2013). Organic

aerosols in the lower stratosphere have been shown to have significant radiative effects (Yu et al., 2016).

The conceptual model proposed here implies a profound difference between the present-day polluted atmosphere and the pristine pre-industrial situation, especially over the continents. In the pristine atmosphere, the gradient of particle number concentrations may have been from high values in the UT to low values in the PBL, as we have found in Amazonia. In polluted continental regions, on the other hand, nucleation and NPF occur predominantly in the lower troposphere, which thus has become the dominant source of atmospheric aerosols in today's atmosphere over much of the world. Consequently, in the anthropocene the aerosol concentration profile has been turned upside down in polluted regions, since now the highest concentrations are found in the PBL.

This has important consequences for the Earth's climate system. The aerosol concentrations in the PBL influence cloud microphysical properties and radiative energy fluxes, which affect the characteristics of convection and thereby influence cloud radiative forcing, atmospheric stability, precipitation, and atmospheric dynamics at all scales (Jiang et al., 2008; Koren et al., 2008; Rosenfeld et al., 2008; Koren et al., 2010; Fan et al., 2012; Rosenfeld et al., 2014; Gonçalves et al., 2015; Stolz et al., 2015; Dagan et al., 2016; Braga et al., 2017). By their radiative and microphysical effects on convection dynamics, aerosols are also able to increase upper tropospheric humidity, which plays an important role in the Earth's radiation budget (Sherwood, 2002; Kottayil and Satheesan, 2015; Riuttanen et al., 2016) and may also affect the potential for aerosol nucleation in the UT, thus providing an additional feedback.

5. Acknowledgments

We thank the entire ACRIDICON-CHUVA team for the great cooperation that made this study possible. Our thanks go especially to the HALO pilots, Steffen Gemsa, Michael Grossrubatscher, and Stefan Grillenbeck, who always worked hard to put the aircraft at the right place for our measurements, even under sometimes difficult conditions. We appreciate the support of the colleagues from enviscope GmbH for their valuable help in certifying and installing the numerous instruments for HALO and thank the HALO team of the DLR for their cooperation. We acknowledge the generous support of the ACRIDICON-CHUVA campaign by the Max Planck

1258 Society, the German Aerospace Center (DLR), FAPESP (São Paulo Research Foundation), and
1259 the German Science Foundation (Deutsche Forschungsgemeinschaft, DFG) within the DFG Pri-
1260 ority Program (SPP 1294) “Atmospheric and Earth System Research with the Research Aircraft
1261 HALO (High Altitude and Long Range Research Aircraft)”. This study was also supported by
1262 EU Project HAIC under FP7-AAT-2012-3.5.1-1 and by the German Science Foundation within

Atmospheric Chemistry and Physics Discussions

[e]) Minimum and maximum temperature at top of most recent deep convection in grid boxes through which the trajectories for the flight leg had passed.
[d]) Trajectories were calculated for each minute of the leg, and for each trajectory the time between sampling and the most recent encounter with DC was determined. Given are the shortest and the longest of these time intervals.
[a]) Minimum and maximum length of time that the trajectories from each leg had spent in grid boxes with DC.

Table 2: Composition of UT aerosols based on AMS and SP2 measurements

Discussion started: 1 August 2017

Atmospheric Chemistry and Physics Discussions

Figure 9: Size spectra: The black line shows the mean boundary layer DMPS size spectrum from a segment in the PBL on flight AC13 (16:55 to 17:18UT). The square black symbols represent the mean, the grey shaded area the standard deviation of the measurements. The line is a logarithmic fit with modal diameters of 74 and 175 nm. The colored lines represent size distributions from 0.65 to 5.8 km from a G1 flight during GoAmazon (Wang et al., 2016a).

Fig. 19: Airmass contacts with deep convection. The colors indicate the cloud top temperature of the convective system with which the trajectory had the most recent contact. The aircraft altitude at which the airmass was sampled is indicated by the red line. The colored dots are plotted at the altitude at which the airmass crossed the grid cell with the convective system. The dots are only plotted if this altitude is greater than 6 km and if it encountered a DC (i.e., $T_b < -30$ ºC). The shaded areas correspond to the flight segments with elevated CN concentrations. a) flight AC09, b) flight AC18.
